Introduction

Nanostructured organosilicates with controlled morphologies have recently been of interest with regard to many potential applications, including nanopatterning [1], which results in materials with applications in microelectronics and photonics. One approach to creating ordered nanostructures is to use block copolymers as templates by taking advantage of microphase separation. The structures formed by this process have been studied in a range of systems in which the chemical composition and resulting structure could be related through a phase diagram, including ordered cylindrical and lamellar structures and disordered aggregations of spheres. Robust silicate nanostructures can be formed by swelling these highly reproducible phases with silicate precursors that can be cured at temperatures below the melting points of the ordered phases. Small-angle x-ray scattering (SAXS) is an important tool for investigating these materials at each stage of their formation.

Methods and Materials

A series of samples was formed by casting and curing mixtures of silicate precursors with solutions of polybutadiene and poly(ethylene oxide) into films 100- to 200- μm thick (Fig. 1). The structures of samples with a variety of compositions produced by a variety of preparations [2] were studied by using SAXS. The samples were examined under ambient conditions at the

end of the chemical process. They showed no signs of degradation following moderate x-ray exposure. SAXS diffraction patterns were obtained by illuminating the samples with a 0.15- to 0.5-mm-diameter incident beam of 10-keV x-rays. The scattered photons were imaged by a liquid-nitrogen-cooled charge-coupled device (CCD) camera at a distance of 75 cm from the sample.

Results

The SAXS experiments show that the microstructure and phase behavior of these nanocomposites are very sensitive to the polymer/matrix interfaces and their compositions. These observations are consistent with results obtained from transmission electron microscopy (TEM) and nuclear magnetic resonance (NMR) measurements [2]. However, for a range of compositions, the diffraction pattern consisted of sharp crystalline reflections that are consistent with the formation of a well-ordered structure with lattice constants of 10 to 20 nm. One such pattern from a phase that can be

described with a 2-D distorted hexagonal lattice of cylindrical structures is shown in Fig. 2. In this case, the casting and curing process resulted in the long axes of the cylinders lying in the plane of the sample. No crystalline reflections were observed with the incident beam along the surface normal of the cast film.

Discussion

The sharp reflections seen in Fig. 2 are a clear sign of long-range order in the organosilicate composites made by swelling block copolymers. Among the challenges to be met in further experiments is to elucidate the origin of the anisotropic structure evident in the distortion of the hexagonal diffraction pattern.

Acknowledgments

Operation of the Michigan-Howard-Lucent Technologies-Bell Labs Collaborative Access Team (MHATT-CAT) sector 7 beamlines at the APS was supported by U.S. Department of Energy (DOE) Grant No. DE-FG02-99ER45743. Use of the APS was supported by the DOE Office of Science, Office of Basic Energy Sciences, under Contract No. W-31-109-ENG-38.
